

DM2200 Temperature Sensor Demonstration

by Frank Perkins

The example application shown in Figure 1 measures temperature using a thermistor-resistor circuit connected to GP6 on a DM2200 field node. The application is written in Microsoft Visual Basic 6.0 (SP6). The sensor used is a Vishay BCcomponents 2322 640 66103 NTC thermistor, which has a nominal resistance of 10K at 77 °F (25 °C). This thermistor is readily available from Digi-Key and other electronic component distributors. The data sheet for the thermistor was located at <http://www.vishay.com/search?query=2322+640+66103&searchChoice=part>. The thermistor is connected between the 3 V regulated output on the DM2200 and the ADC input, and a 10K, 1% resistor is connected from the ADC input to ground. The thermistor and the 10K resistor form a voltage divider to drive the ADC input, where the voltage increases with increasing temperature, as shown in Figure 2. The photograph in Figure 3 shows the thermistor and resistor installed on an IM2200 interface module.

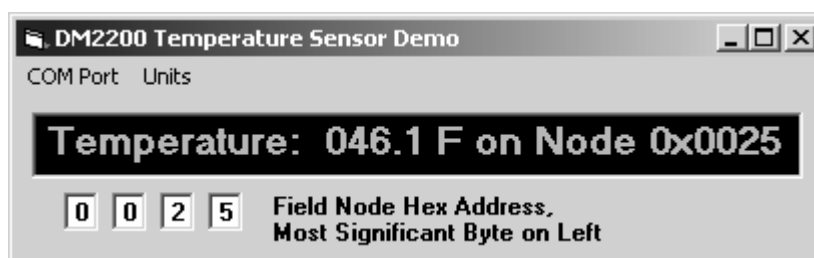

Figure 1: DM2200 Themistor Demo

The example program is contained in a single Visual Basic form. The heart of the program is *Timer1_Timer*, which is launched once every two seconds by a timer control. This routine first checks the serial port input buffer. If the input buffer is holding one or more bytes, the *GetRX* subroutine is called to collect and process them. *Timer1_Timer* then calls *TXCmd* to output a *CMD_IO IO_ADC* (read ADC), which propagates through the DM2200 network to the addressed field node. The field nodes makes the ADC measurement and sends a response back to be read on the next *Timer1_Timer* cycle.

Each time *GetRX* is called, it collects the newly received bytes in *ComData\$* and calls *RXRsp*. The function of *RXRsp* is to extract messages from the stream of received bytes. *RXRsp* adds *ComData\$* to the end of the *FIFO\$* string. The *FIFO\$* string is then scanned and complete messages are extracted. Any partial message at the end of the *FIFO\$* string is saved for future processing.

Each time *RXRsp* extracts a complete network message, it calls *ShowT*. This subroutine filters out all network messages except *CMD_IO IO_ADC* response messages. The ADC measurements are then converted to temperature readings and displayed. The *GetTemp* subroutine does the temperature conversion using the *TmpArry* table values and interpolation. The *TmpArry* table values were derived from a resistance versus temperature table in the BCcomponents data sheet. These resistance

values were, in turn, used to compute the *TmpArray* table of output voltage ratios, in terms of ADC counts, for the thermistor-resistor voltage divider.

TXCmd builds and sends command messages. When the application is started and a valid COM port is entered, a *CMD_MASTER* (enable master beacon) is immediately sent. Then *TXCmd* sends commands to disable network sleep mode and to set the master beacon interval to 10 seconds. Following these initialization messages, *TXCmd* sends *CMD_IO IO_ADC* messages every two seconds. Note that the *op_ref* (message ID) byte is changed for every transmitted message. This is required for normal network operation.

Figure 2: ADC Count₁₀ versus Temperature in °F

The temperature sensor example has been kept simple to avoid obscuring the basic DM2200 network command-response program methodology. Nevertheless, this simple program can be used to remotely monitor a temperatures over an outdoor path of more than a mile using the four nodes in the DM2200-916-DK development kit..

After the application is installed, launch it and select the COM port. For PCs with a serial port, this is usually *COM1*. In the case of USB operation, a virtual COM port is assigned to the IM2200 USB port by the associated USB virtual COM port driver. *COM5* is shown in the example in Figure 4. Next enter the address of the field node that has the

thermistor-resistor voltage divider installed (*Node 0x0025* is shown in Figure 1). The *Units* menu selects Fahrenheit or Celsius for the temperature display.
